Obesity and Weight Management in the Elderly

Geriatric Medicine Academic Grand Rounds
October 17, 2012
Dr. Hélène O’Connor, MD, MSc, CCFP
Care of Elderly Fellow, University of Ottawa
Objectives

- Is obesity in the elderly a problem (or a growing problem)?
- How is obesity in the elderly measured/defined?
- What impact does weight/BMI have on health (morbidity / mortality) – is it protective or harmful in the elderly?
- Is voluntary weight loss beneficial to the health of the elderly and should we recommend it for our patients?
What is the prevalence of obesity among the elderly and what is the trend?
Obesity Prevalence

- Obesity on the rise in all age categories
- Number of obese elderly also increasing
  - Increase in total number of elderly
  - Increase in % of elderly who are obese
  - Mortality among obese adults decreasing in the last decades (better health care, etc...)
United States Overweight and Obesity Levels, 1971-2006

NOTES: Overweight (not including obese) is defined as a body mass index (BMI) greater than or equal to 25 but less than 30 and obese as a BMI greater than or equal to 30. See data table for Figure 7 for estimates for children, data points graphed, standard errors, and additional notes.

SOURCE: CDC/NCHS, National Health and Nutrition Examination Survey.
Data from the National Health and Nutrition Examination Survey, 2009–2010 (USA)

- More than 1/3rd (35.7%) of adults and almost 17% of youth were obese.
- Adults aged 60+ were more likely to be obese than younger adults – with 39.7% of those 60 yoa and over as obese.
- Healthy People 2010 (initiative developed in 2005)
  - Goal of 15% obesity in ≥60yoa group
  - Projections according to trends
    - Best case scenario: 33.6% by 2010
    - Worse case scenario: 39.6% by 2010

Significant increasing linear trend by age ($p < 0.01$).
Significant increasing linear trend by age ($p < 0.001$).

NOTE: Estimates were age adjusted by the direct method to the 2000 U.S. Census population using the age groups 20–39, 40–59, and 60 and over.

Figure 5. US and UK population projections 2010 vs 2030, by overweight or obesity status, assuming historic trend in BMI. A=USA, 2010; B=USA, 2030; C=UK, 2010; D= UK, 2030. Population pyramid. **Size of bars shows the size of projected census population (×100 000) by BMI status, sex, and age category in USA and UK.**

• How is obesity defined / measured in the elderly?
Definition of Obesity

- **Unhealthy excess of body fat which increases the risk of medical illness and premature mortality**
  - Strong links between obesity and disability and life-threatening diseases such as diabetes, heart disease, stroke, and multiple types of cancer

- **Gold standard for definition of obesity (WHO):**
  - obesity = Body Fat > 25% in men and > 35% in women
  - Where BF % = \(\{\text{weight-FFM/weight}\} \times 100\)
    - (use resistance data from bioelectrical impedance analyzers)

- **Use various formulas to estimate body fat:**
  - BMI (body mass index)
  - WC (waist circumference)
  - WHR (waist hip ratio)
  - Others…
Measuring Obesity

• Body Mass Index:

\[
\text{BMI} = \frac{\text{weight}\,(\text{kg})}{\text{height}^2\,(\text{m}^2)}
\]

Estimation of % body fat from total body mass, which is then correlated with health risks: excess adipose tissue linked to DM, CAD, cancer, etc…

Recommended by NIH and WHO for use in clinical practice for classifying medical risk by weight status and management of weight loss/weight control.
Limitations of BMI in General Population

- Variable sensitivity / specificity at different BMI cut-offs / age/ gender (false pos/neg)
- Doesn’t account for differences in body composition:
  - Doesn't differentiate between adipose tissue and lean body mass (which have opposite effects on health)
  - In children and the elderly, differences in bone density and, thus, in the proportion of bone to total weight can mean the number at which these people are considered *underweight* should be adjusted downward.
BMI in the elderly

- Limitations in the elderly:
  - a) Height decreases
  - b) Body composition changes (decrease in FFM and increase / redistribution of FM)

- Body composition changes tend to underestimate fatness vs loss of height tends to overestimate fatness
  - i.e. falsely elevated BMI b/c decreasing height and falsely decreased BMI b/c of changes to body composition

\[
\text{BMI} = \frac{\text{weight (kg)}}{\text{height}^2 (\text{m}^2)}
\]
Changes in body weight and composition with aging

- **BMI** gradually increase during most of adult life and peak at 50-59yoa, then tends to decrease:
- **Body fat mass** increases up to 75yoa and then decreases or remains stable (Hickson M, 2005)
- Abdominal circumference increased 0.7cm/year among 1300 Swedish women (no difference across age strata)
- **Distribution of Body Fat**
  - Fat redistributed centrally (intra-abdo), intramuscular fat and intrahepatic fat also increase*
- **Fat Free Mass (muscle, organ tissue, skin, bone)**
  - Decreases (up to 40%) with age starting around 40-50yoa (some say FFM peaks at 20yoa)
How/ why we get fatter as we age: Energy Imbalance

- **Lower basal metabolic rate / energy imbalance**: sarcopenia and ageing per se result in lower BMR.
  - Obesity usually develops slowly, e.g. 1 kg/year, through very small (undetectable) energy imbalance

- **Increased sedentary lifestyle** – retirement, decreased activity around home, co-morbidities limiting PA (COPD, OA, etc..)

- **Medications:**

- Other complex behavioural, psychological, social and metabolic factors.
So, it's fairly safe to say that as we get older we are relatively fatter than our BMI would indicate – but does this have any impact on our health???

*Health consequences of changing body composition*

- Central distribution of fat is associated with increased risk of stroke, diabetes, hyperlipidemia, heart disease and HTN
- Redistribution of fat into muscles and liver increase risk for insulin resistance and metabolic disease / DM2

Based on studies done in middle aged adults
Are the risks associated with obesity in the general adult population also applicable in the elderly?
Obesity in the Elderly: Morbidity

Obesity increases an elderly individual’s susceptibility to disability and poor outcomes, leading to poor quality of life and increased demand for health care services.

- HTN, DM2, CVD, CVA
- OA
- GERD
-Obstructive sleep apnea
- Urinary incontinence
- Erectile dysfunction
- Cataracts
- Cancer (breast, colon)
- Dementia*
- Chronic pain
- Decreased Physical function / Frailty
Obesity and Frailty

- Frailty = Reduction in physiologic reserves severe enough to cause disability / impair function
- 96% of community living 65-80yo with BMI’s ≥ 30 were frail
- Leads to limitations to basic ADLs
  - Older persons who are obese (BMI >30) have a greater rate of nursing home admissions than non-obese counterparts (Zizza CA, etal. 2002)
Can obesity be good for us?

- Increased BMI can also mean increased Free Fat Mass (FFM)
  - Increased BMD, decreased OP and hip#s in older men and women
- May be protective against dementia
- Energy reserves in case of illness
- May be associated with reduced mortality
The evidence thus far…

“The mortality-obesity association is estimated to diminish with age, so as to suggest, for example, that for middle-aged people (age 40–65 years) obesity is a significant risk factor for mortality, but for older people (age ≥65 years) it is not significantly associated with increased mortality risk—or, as some evidence suggests, might even confer a survival advantage.

Obesity in the Elderly: Mortality

- Overweight / higher BMI associated with lower risk of mortality in elderly
- The BMI associated with the lowest mortality is slighter higher in the older population vs younger

The Obesity Paradox

Being overweight or obese is associated with better long-term survival than being normal weight

- In various populations
  - Elderly
  - CKD with HD
  - COPD
  - Cancer
  - CAD, Heart Failure
  - HIV
  - RA

Two hypotheses:
1) Excess fat in and of itself favors survival
2) Excess fat is associated with some other surrogate marker of another protective factor(s) – i.e. nutritional status, fitness, lean / fat free body mass

Oreopoulos et al., 2009

Are the health risks associated with obesity in the elderly really lower than in adults?

A closer look at the Obesity Paradox (and the epidemiological studies that are de-bunking it)

Oreopoulos, 2009
Many large population-based studies suggest risk of obesity on mortality declines with age.

But, institutionalized people excluded from these surveys
- Obesity ↑ risk of institutionalization (esp. in elderly)
- Obesity ↑ risk of mortality
- So, healthy elderly obese end up in these studies

New study corrects for that, and finds that risk of obesity on mortality actually ↑ with age
- BMI 30-34: OR = 1.4-1.6 age 65+
- BMI 35-39: OR = 1.8-2.0 age 65+
- BMI 40+: OR = 2.6-3.7 age 65+
Fat Distribution

- 5000 people 65yoa or older followed for 5 yrs
- Both BMI and WC were inversely related to mortality
- High WC was associated with higher mortality when BMI was controlled
- High BMI was associated with lower mortality risk after controlling for WC
Importance of Midlife Obesity

What do we know about intentional / unintentional weight loss and weight management in the elderly?
Unintentional weight loss: Etiology

- **Wasting**: inadequate dietary intake
  - d/t disease, psychosocial factors, loss of appetite

- **Cachexia**: involuntary loss of FFM or BCM (body cell mass) caused by catabolism
  - Presence of an acute immune response
  - Characterized by raised BMR and increased protein degradation

- **Sarcopenia**: involuntary loss of muscle mass
  - May be intrinsic part of ageing, lack of physical activity
  - Biochemical component: GH, testosterone, estrogen, cytokines, neuronal loss from SC with ageing

Current weight management recommendations for all adults

Lifestyle Management (Overweight & Obese Class 1-3)

- Advise patients on strategies for achieving and maintaining a healthy weight using diet and exercise. Refer the patient to a weight loss program, if the program meets the following criteria:
  - Based on a balanced healthy diet (e.g., 500-1000 kcal/day deficit);
  - Encourages regular physical activity;
  - Expects people to lose no more than 0.5-1 kg (1-2 lb) a week; and
  - Establishes an initial weight loss goal of 5-10% of the original weight.

NICE, 2006
Lau DCW et al., CMAJ 2007
Weight loss in the elderly

- Not usually recommended
- Weight loss / variations associated with increased mortality and disability in the elderly
  - Based on observational studies
  - Many of these studies don’t differentiate between intentional vs. unintentional weight loss

Intentional weight loss in the Elderly

Risks
- Malnutrition
- Loss of weight = further loss of muscle mass and bone density
- Loss of metabolic reserves against disease

Benefits
- Improved / normalized metabolic abnormalities
- Improve physical function and quality of life
- Beneficial or neutral effect on mortality
Intentional weight loss in the Elderly

- 25% of diet induced weight loss will be composed of FFM (regardless of age)
- Adding endurance or resistance training to a diet program helps to preserve FFM during intentional weight loss
  - meta-analysis showed that exercise cuts number down by half from 25% to 12% loss of FFM
- RCT conducted in 65-80yos
  - no difference in loss of FFM after a 10% diet induced weight loss + regular exercise vs with the control group who did not lose weight – so exercise can attenuate diet-induced loss of FFM
- Bone density – 1-2% bone loss with a weight loss of about 10% over a 4-18 month period
  - weight loss increases markers of bone turnover and plasma concentration of hormones involved in bone metabolism
- Exercise can attenuate bone loss
  - ensuring sufficient calcium and vit D should help to preserve BMD
Benefits of Intentional weight loss

**ADAPT**: RCT, n=318, mean age 69, overweight /obese, 18-month weight loss intervention
- Better physical function in overweight patients with knee OA,
- 50% lower mortality rate over 8yrs of f/u (HR: 0.5; 95% CI: 0.3, 0.9)

Loeser SP, et al. 2004; Shea MK, et al., 2010

---

**TONE**: effect of intentional weight loss on all-cause mortality – RCT, mean age 66yrs, 12 yr f/u
- Improved MMSE scores with ave wgt loss 10% (p < 0.05)
- 30% reduction in Dx and Tx of HTN, CV events over 2.4yrs
- No significant different in all-cause mortality

Fatness vs Fitness

  - Fitness altered obesity paradox
  - Underweight men with low fitness had highest mortality risk vs highly fit overweight men had lowest
Can we improve how we measure obesity / body fat in the elderly?
Recommendations

• Improving our estimation of body fat/nutritional status
  ◦ Obtain more accurate BMI:
    • Improved estimate of height (arm span or knee height have been suggested but yet to be validated) – (villareal et al)
    • More research into appropriate cut-offs/targets for elderly
  ◦ Use other surrogate measures of body fat:
    • Waist-Hip-Ratio
    • Waist Circumference,
    • Mid-arm circumference
    • Radiological measurements of body fat compartments
      • CT, Dual-energy X-ray absorptiometry (accurate but not feasible)

**Waist Circumference**

- Easy to measure
- Strongly related to both visceral and total fat (as evaluated by CT) – i.e. Fat distribution
- Body composition more important than BMI in determining mortality risk associated with obesity in older adults
- Cut-off points of 102 in men and 88cm in women are used in adults and need to be validated in elderly population
Waist-Hip-Ratio

- WHR has been found to be an efficient predictor of mortality in older people than waist circumference or BMI. (JE DeCaria et al., Int Journal Obesity, 2012; Oreopolous)
- More room for error and 2 measurements instead of one (WC)

**Measurement of waist hip ratio:** In a lean person (left), the waist can be measured at its narrowest point, while for a person with convex waist (right), it may be measured at about one inch above the navel. The hip is measured at its widest portion of the buttocks at left, and at the great trochanters at right.
Clinical implications
What’s the right BMI for the elderly?

- Established Populations for Epidemiologic Studies of Elderly
  - Followed 12,725 Americans >=65yoa for 7 yrs
  - Disability-free life expectancy was found to be greatest among people with BMI 25-30

- BMI associated with lowest rate of decline of physical function: 23-30
  - Oreopoulos, 2009
yes, yes, yes - now seriously - what can we do to improve our health?

1. Exercise
2. Exercise
3. Exercise
4. Exercise
5. Exercise
6. Exercise
7. Exercise
8. etc.
Weight loss or maintenance

- **Emphasize Exercise**: to improve strength, balance, endurance and minimize muscle/bone loss and prevent functional decline
- Dietary changes to improved *nutritional status* over weight loss
- **Modest weight reduction** (5%-10%) may be beneficial
  - Positive or neutral effect on mortality
  - Positive effect on function / QOL: GERD, OSA, OA, mobility, pain, HTN (Zamboni et al)
- **Target BMI**: 25-30 (lower range for M, higher for W)
Weight loss or maintenance

- **Individualized** as per patient’s comorbidities, functional status and living situation
- Importance of **mid-life obesity** on long-term mortality risk: encourage weight loss in middle-age
- Always investigate **unintentional** weight loss
- Being **underweight** is associated with increased mortality at any age; in the elderly being underweight poses far greater risk than being overweight
Resources in Ottawa

- **Forever young:**
  - Group exercise / physio program
  - Covered by OHIP
  - For seniors in RH or living ind.
- **CCAC – OT / PT assessment**
- **Falls clinic: Montfort Hospital**
- **Geriatric Day Hospital**
  - EBH: 2xwk physio/exercise
- **Cardiac or Pulmonary Rehab Programs**
  (TOH, Montfort)
Next steps:

- Consensus on the definition of obesity in the elderly
  - Improving measurement/surrogate estimate (BMI vs WC vs WHR)
- Better understanding of the effect of obesity on mortality/morbidity and the Obesity Paradox
- Look at sarcopenic obesity and its clinical implications on mortality
- Better understanding of effects of voluntary weight loss
- Understanding the gender differences in estimating obesity and mortality in elderly
- Approach to intentional weight loss in the elderly to minimize risks and help improve overall function
