Prescribing exercise interventions for patients with chronic conditions

Tammy C. Hoffmann BOccThy (Hons 1) PhD, Chris G. Maher BAppSc(Phty) PhD, Tom Briffa BPhysEd PhD, Catherine Sherrington BAppSc(Physio) PhD, Kim Bennell BAppSci(Physio) PhD, Jennifer Alison MSc PhD, Maria Fiatarone Singh MD, Paul P. Glasziou MBBS PhD

Exercise has been shown to be beneficial in the treatment of many chronic conditions. Mortality benefits from exercise are similar to pharmacologic interventions for secondary prevention of coronary heart disease, stroke rehabilitation, treatment for heart failure and prevention of diabetes. The morbidity benefits of exercise for diseases that are not life-threatening, such as back pain and osteoarthritis, are substantial. However, exercise is underprescribed and frequently overlooked, often in favour of a pharmacologic or surgical intervention.

Factors that contribute to underprescription of exercise interventions may include a lack of awareness among many clinicians and patients about the effectiveness of exercise interventions, poor knowledge about what comprises an effective exercise intervention, a lack of relevant training and educational opportunities available to medical practitioners, and inadequate descriptions of exercise interventions in published trials and reviews. An analysis of 137 nonpharmacologic interventions from 133 trials found that 61% did not have sufficient information reported (e.g., procedural and intensity details) to enable replication in practice, thus preventing clinicians from being able to prescribe these interventions. An analysis of the reporting of the exercise component used in cardiac rehabilitation trials found that adequate descriptions of the exercise schedule were missing for 58% of the interventions.

We summarize evidence of benefit for using exercise for some key chronic conditions, highlight key outcomes shown to be influenced by exercise and provide a guide to the practical how-to details for an effective disease-specific exercise. We discuss conditions that were selected for their high disability burden and the strength of the evidence for the effectiveness of exercise in managing the condition. The search process we used to locate the evidence presented in this paper is provided in Box 1.

Outcomes for which exercise is effective

We review the evidence for the effectiveness of exercise interventions for osteoarthritis of the hip and knee, chronic nonspecific low-back pain, prevention of falls, heart failure, coronary heart disease, chronic obstructive pulmonary disease (COPD), chronic fatigue syndrome and type 2 diabetes (Appendix 2, available at www.cmaj.ca/lookup/suppl/doi:10.1503/cmaj.150684/-/DC1). We present the key clinical and health utilization outcomes that exercise interventions have been shown to affect and not affect in detail.

Simply prescribing exercise, in a generic sense, to a patient is insufficient guidance and is

Competing interests: None declared.

Box 1: Evidence used in this review

We each contributed to the review by our specialty. We searched PubMed and the Cochrane Library for publications from 2000 to February 2015, using methodological filters (for systematic reviews and randomized controlled trials [RCTs]) and a combination of medical subject headings and free-text terms (Appendix 1, available at www.cmaj.ca/lookup/suppl/doi:10.1503/cmaj.150684/-/DC1). The information presented in this article is based on evidence from systematic reviews, if available, or RCTs.

KEY POINTS

- Exercise is beneficial for many chronic conditions and can offer benefits that are comparable to pharmacologic interventions, yet exercise is underprescribed.
- Like medication and surgery, exercise is not a single entity and must be tailored to the condition. Exercise must be appropriately implemented to achieve outcomes that are consistent with those reported in intervention trials.
- To prescribe exercise for chronic conditions, clinicians must know sufficient details about the appropriate and effective exercise interventions and their components.
- We describe and discuss the evidence of effectiveness of exercise interventions for the following chronic conditions: osteoarthritis of the hip and knee, chronic nonspecific low back pain, prevention of falls, heart failure, coronary heart disease, chronic obstructive pulmonary disease, chronic fatigue syndrome and type 2 diabetes.
unlikely to achieve the desired outcomes. To help clinicians prescribe evidence-based exercise interventions, we provide practical details for some conditions in Boxes 2–4 (low-back pain, COPD, diabetes) and Appendices 3–6 (osteoarthritis, falls prevention, chronic fatigue syndrome, heart disease; available at www.cmaj.ca/lookup/suppl/doi/10.1503/cmaj.150684/-/DC1). Where possible, we chose a single intervention for each condition that had evidence of effectiveness and for which adequate details of the intervention were available. Where this was not possible, a typical intervention or a range of practical details from various studies are presented. The information about each intervention is presented using key headings from the TIDieR (Template for Intervention Description and Replication) guide for intervention reporting. Some of these interventions may be prescribed by family physicians and largely self-actioned by a patient (e.g., for falls prevention), whereas other interventions require a referral to a health care professional with expertise in exercise prescription (e.g., cardiac rehabilitation, exercise for chronic back pain or knee osteoarthritis and pulmonary rehabilitation for COPD).

Box 2: Exercise for chronic nonspecific low-back pain

**Rationale for exercise:** Each type of exercise has a different rationale. The two main types that can be used are motor control exercises and graded activity.

**Motor control exercise:** Aims to retrain control of the trunk muscles, posture and movement patterns, using principles of motor learning such as segmentation and simplification. A detailed assessment of recruitment of the trunk muscles, posture, movement pattern and breathing guides the specific treatment for each patient. As control is regained, the exercises progress to more functional activities. Exercises are typically guided by pain and are mostly performed pain-free.

**Graded activity:** Aims to improve a patient’s ability to complete functional activities and incorporates principles from cognitive behavioural therapy and exercise science. The program addresses physical impairments, such as impaired endurance, muscle strength and balance, but also considers psychological barriers to activity resumption, such as pain-related fear, low self-efficacy or misunderstandings about back pain. Principles of cognitive behavioural therapy, such as pacing, goal setting and self-reinforcement, are used. Exercises are progressed in a time-contingent rather than pain-contingent fashion.

**Provider:** Physiotherapist

**Mode:** Individual, supervised face-to-face sessions (and exercise practice at home)

**Where:** Primary care physiotherapy clinic

**Materials needed:** Simple equipment found in a typical physiotherapy gym

**Number of exercise sessions:** 14 sessions

**Schedule details:** A typical program would comprise 12 sessions over an 8-week period, with 2 booster sessions at 4 and 10 months follow-up plus a concurrent home program.

**Duration of each session:** Sessions of 1 hour in duration

**General considerations**

Although there are few absolute contraindications to prescribing exercise for people with chronic conditions, it is important that patients receive a proper assessment by a physician before starting an exercise program. General considerations include an initial supervision period for most conditions, education about what the exercise program involves and how it can help, an understanding of the patient’s fears and beliefs (for many conditions, such as low-back pain, cardiac conditions, COPD and chronic fatigue syndrome) and incorporation of strategies that enhance longer-term adherence.

**Osteoarthritis of the hip and knee**

Exercise is beneficial for improving pain and function in patients with hip or knee osteoarthritis, regardless of their age, disease severity, pain or functional level. It is important to ensure patients understand that osteoarthritis is not a wear-and-tear disease and that discomfort or pain during exercise does not indicate further damage to the joint. A range of exercise types is suitable for patients with osteoarthritis, including muscle strengthening, and aerobic and range-of-motion exercise. Exercise can be performed on land or in water. Supervised exercise that is supplemented with a home exercise program is preferable where possible. For those who are overweight or obese, combining exercise with weight loss is more effective than either treatment alone.

Structured land-based exercises, usually delivered by a physiotherapist, are described in Appendix 3.

**Evidence of benefit**

For osteoarthritis of the knee, a recent Cochrane review of 54 randomized controlled trials (RCTs) that compared a range of land-based exercises with no-exercise controls showed evidence of benefit. Of these trials, 19 were considered at low risk of bias. Evidence for the immediate benefits on mean pain scores was high quality (44 RCTs involving 3527 participants), and the effect size was considered moderate (standardized mean difference [SMD] –0.49, 95% confidence interval [CI] –0.39 to –0.59) lower in intervention groups; absolute reduction of 12 points [95% CI 10–15] on a 0–100 scale, where 0 represented no pain, compared with control groups). Evidence for the effect on physical function was of moderate quality (44 RCTs involving 3913 participants), was improved in the intervention groups (SMD –0.52, 95% CI –0.39 to –0.64; absolute improvement of 10 points [95% CI 8–13] on a 0–100 scale, where 0 represented no physical disability) and likely of clinical significance. At two to six months after the conclusion
of the exercise intervention, the benefits were less extensive but still significant, and after six months, benefits for pain reduction were not maintained, but small benefits (improvement of 4 points, 95% CI 2 to 6) remained for physical function. Exercise effects on quality of life (QoL) (13 RCTs involving 1073 participants) were considered small (SMD 0.28, 95% CI 0.15 to 0.40; absolute change of 4 points [95% CI 2 to 5] on a 0–100 scale [100 was the maximum quality of life]).

For osteoarthritis of the hip, a recent Cochrane review of 10 RCTs of land-based exercise compared with no exercise (of which seven were deemed to have a low risk of bias) showed evidence of benefit.11 High-quality evidence from nine trials (549 participants) showed that, immediately after treatment, exercise reduced pain (SMD –0.38, 95% CI –0.55 to –0.20), with an absolute reduction of 8 points (95% CI 4 to 11) on a 0–100 scale (a lower score was better). There was also high-quality evidence (nine RCTs involving 521 participants) that exercise improved physical function immediately after treatment (SMD –0.33, 95% CI –0.54 to –0.05), with an absolute decrease of 7 points (95% CI 1 to 12) on a 0–100 scale (a lower score was better). The benefits for pain and physical function were sustained to at least three to six months after the exercise interventions. Only three small studies (183 participants) evaluated the effect of exercise on QoL, with overall low-quality evidence showing no benefit (SMD 0.07, 95% CI –0.23 to 0.36). The well-documented strong placebo effects for self-reported outcomes in osteoarthritis have not been controlled for in most studies of exercise, because participants have not been blinded to group allocation. Therefore, the exact amounts of beneficial effects directly arising from exercise cannot be determined.

Contraindications

For patients with osteoarthritis of the hip or knee, there are no absolute contraindications to prescribing exercise, although comorbidities need to be taken into account. If the joint is acutely inflamed, the exercise program may need to be modified.

Adverse effects

Studies report few adverse events associated with exercise for osteoarthritis, and they are generally minor, usually increased pain or pain at other sites.10,11

Chronic nonspecific low-back pain

A typical program would comprise 20 hours of individually supervised sessions over 8–12 weeks and a home program.25 The type of exercise (e.g., yoga v. graded activity) seems less important than the quality of implementation (e.g., supervision, inclusion of a home program and duration of the program have been shown to improve treatment effect).25 Exercise programs normally include an education component, incorporation of psychological principles, such as pacing or goal setting, and progress in functional activities.12,25 Many programs also explicitly address psychological characteristics, such as catastrophizing, pain self-efficacy and fear of injury/movement, that can be barriers to engaging in physical activity.12 Motor control exercises and graded activity as delivered by a physiotherapist are described in Box 2.

Evidence of benefit

In a Cochrane review of exercise for low-back pain, 43 RCTs involving patients with chronic low-back pain were included.26 In a meta-analysis of eight RCTs (n = 370), there was mean improvement of pain at earliest follow-up in the exercise group when compared with the control group (10.2 points, 95% CI 1.3 to 19.1) on a 0–100 pain scale.26 A companion meta-regression study by the same authors found that the effect of exercise was associated with exercise program characteristics, such as supervision, high dose (> 20 h) and individually designed programs. The authors estimated that an exercise program incorporating the most effective intervention characteristics would provide a larger effect size on pain of 18.1 points (95% CI 11.1 to 25.0) and an effect on function of 5.5 points (95% CI 0.5 to 10.5) on a 0–100 function scale.25 These effects are modest, although they are similar in size to that provided by other treatments. For example, a Cochrane review of nonsteroidal anti-inflammatory drugs reported an improvement in pain of 12.4 points (95% CI 9.3 to 15.5).27 For patients with acute low-back pain, there was no significant difference between exercise groups and control groups for pain and function at earliest follow-up (three RCTs, n = 491). The Cochrane review was confined to pain and function outcomes and did not provide information on other outcomes, such as QoL, work status or prevention of future recurrence. This Cochrane review also did not use the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach (available at www.gradeworkinggroup.org) to describe the overall quality of the evidence.

Contraindications

Exercise is contraindicated in patients with low-back pain arising from a serious medical condition, such as fracture, infection, cancer or cauda equina syndrome. These conditions should be ruled out before prescribing an exercise program.

CMAJ 3
Adverse effects

The Cochrane review of exercise for low-back pain did not provide data on adverse effects.\(^2\) In addition to the potential adverse effects of exercise in general, when exercise is used to manage low-back pain the most commonly reported adverse effect is temporary exacerbation of the back pain. In a placebo-controlled trial of motor control exercise (with 77 participants in each group), three participants in the exercise arm reported temporary exacerbation of the pain compared with two in the placebo group.\(^2\)

Prevention of falls

Well-designed exercise programs can prevent falls in community-living older adults\(^1\) when delivered as a single intervention or as part of a multifaceted program.\(^2\) More effective programs include a focus on improving balance\(^1\) (postural control), which has been identified as a key risk factor for falls.\(^3\) Preventive exercise for community-living older adults is discussed in Appendix 4.

Evidence of benefit

In a 2012 Cochrane review, exercise as a single intervention was found to reduce the rate of falls by 30% in intervention groups when compared with control groups.\(^2\) Both group- and home-based exercise that targeted balance, strength and/ or fitness was found to be effective (rate ratio for group-based exercise 0.71, 95% CI 0.63 to 0.82, in 16 RCTs involving 3622 participants; rate ratio for home-based exercise 0.68, 95% CI 0.58 to 0.80, in seven RCTs involving 951 participants). Tai Chi was also found to reduce the risk of falling (the proportion of people falling) by 30% (risk ratio [RR] 0.71, 95% CI 0.57 to 0.87, in six RCTs involving 1625 participants).\(^2\) Individual trials of exercise interventions have not been large enough to test exercise as a strategy for prevention of fractures, but some meta-analyses have suggested that exercise can prevent falls causing injuries\(^1\),\(^2\),\(^3\),\(^4\) (rate ratio 0.63, 95% CI 0.51 to 0.77; 10 RCTs).\(^4\)

Exercise as a single intervention has not been found to be effective in individuals with major risk factors for falls that are not amenable to change with exercise, such as patients with marked visual impairment or those taking psychoactive medications.\(^2\) It appears from the Cochrane review that other evidence-based interventions for the prevention of falls should be prioritized in some patients. For example, the primary intervention for the prevention of falls in patients with marked visual impairment should be a home safety assessment or removal of cataracts. A gradual withdrawal of psychoactive medication should be attempted first in patients who are taking these medications.\(^2\) These populations are likely to receive other benefits from exercise programs. Exercise as a single intervention was not found to be an effective prevention strategy for falls in patients living in high-support care facilities.\(^2\)

Contraindications

There are no absolute contraindications to exercise for the prevention of falls; however, older adults at risk of falling may also have comorbidities (e.g., heart disease); therefore, contraindications outlined elsewhere in this review may be relevant.

Adverse effects

Patients with COPD should be referred to pulmonary rehabilitation\(^3\) when the condition is stable\(^4\) or following a hospital admission for an acute exacerbation.\(^5\) Patients should be taught how to manage symptoms during exercise, especially how to manage breathlessness. Box 3 describes pulmonary rehabilitation.

Evidence of benefit

The evidence for pulmonary rehabilitation comes from two Cochrane reviews — one for patients with stable COPD\(^4\) and one following hospital admission for an acute exacerbation of COPD.\(^5\) The review of pulmonary rehabilitation compared with usual care or no exercise training in patients with stable COPD (65 RCTs involving 3822 participants) found improvement in those who received pulmonary rehabilitation for a number of outcomes. There was moderate-quality evidence for the effect of pulmonary rehabilitation on QoL (MD –6.9 points, 95% CI –9.3 to –4.5, on the total score for the St. George’s Respiratory Questionnaire),\(^3\) in favour of the intervention group (a lower score is better). This effect size exceeded a minimal important difference (MID) of –4 points.\(^4\) There were similar findings for other measures of
QoL (see Appendix 2). Maximal exercise capacity improved in the intervention groups (MD 6.8 watt [W], 95% CI 1.9 to 11.7), which exceeded the MID of 4 W, although evidence quality was rated as low (16 RCTs involving 779 participants). Functional exercise capacity (measured by the six-minute walk test) also improved in the pulmonary rehabilitation groups (MD 43.9 m, 95% CI 32.6 to 55.2). This value was greater than the MID of 30 m (95% CI 25 to 33), but the evidence quality was rated as very low.

In the second review (nine RCTs involving 432 participants) of patients with COPD who were randomly assigned to pulmonary rehabilitation or usual care after hospital admission for an acute exacerbation of COPD, the intervention group experienced a reduction in mortality (odds ratio [OR] 0.29, 95% CI 0.10 to 0.84) and hospital readmissions (OR 0.2, 95% CI 0.08 to 0.6; number needed to treat 4, 95% CI 3 to 8). Overall, the trials were rated as moderate quality.

**Contraindications**

There are few absolute contraindications to exercise training within a pulmonary rehabilitation program. Most physical and medical comorbidities can be managed by expert clinicians; however, unstable cardiac disease may put patients at risk, and participation may not be possible for those with severe arthritis or severe neurologic or cognitive disorders.

**Adverse effects**

No adverse effects from pulmonary rehabilitation were reported in trials included in either of the Cochrane reviews.

**Type 2 diabetes**

Evidence supports aerobic exercise, progressive resistance training, or a combination of the two, when it is structured (defined as planned, individualized and supervised) for the improvement of glycemic control. Given the relative equivalency of metabolic benefits across aerobic and resistance exercise modalities, choice of exercise modality should be driven by patient choice or preference, and presence and type of comorbidities. For example, the presence of sarcopenia, mobility impairment, osteoporosis, frailty and osteoarthritis would suggest using resistance training rather than aerobic exercises, especially if the risk of falling is also present. Severe peripheral neuropathy or peripheral vascular disease with foot ulcers may also preclude weight-bearing aerobic exercise but still allows for resistance training to occur. There is a dose–response relation, with better outcomes associated with an exercise duration greater than 150 minutes per week and higher intensity resistance training. Exercise does not have to be performed in one session for benefits to accrue. Exercise for patients with diabetes is discussed in Box 4.

**Evidence of benefit**

A comprehensive meta-analysis of exercise efficacy for glycemic control in participants with type 2 diabetes that included 47 RCTs (8538 patients) found that structured, supervised exercise training of at least 12 weeks duration (23 RCTs involving aerobic and/or resistance training) was associated with a decline in glycated hemoglobin (HbA1c) level (−0.67%, 95% CI −0.84% to −0.49%) compared with participants in the control group. Similar benefits, when compared with the control groups, were also found for aerobic exercise (−0.73%, 95% CI

---

**Box 3: Exercise for patients with chronic obstructive pulmonary disease**

**Rationale for exercise:** To improve exercise capacity and quality of life, and to reduce breathlessness, hospital admissions and length of hospital stay.

**Provider:** Physiotherapist or exercise physiologist trained in pulmonary rehabilitation and holding current cardiopulmonary resuscitation (CPR) certification

**Mode:** Exercise prescription should be individually tailored based on initial assessment; however, a number of patients can be supervised at the same time. It should be delivered face-to-face, although some sessions can be performed unsupervised at home.

**Where:** Hospital outpatient departments; appropriate community facilities

**Materials needed:** Flat walking track (preferably indoor and air-conditioned), resistance bands, hand weights and pulse oximeter. Optional: stationary cycle ergometer, treadmill, fixed-weight machines and supplemental oxygen. Assessment tools: Six-minute walk test (6MWT) procedures and instructions, dyspnea scale, pulse oximeter, device to measure blood pressure, spirometer, disease-specific quality of life questionnaire (e.g., St. George’s Respiratory Questionnaire or Chronic Respiratory Disease Questionnaire). Assessment: Spirometry; resting blood pressure, heart rate and oxygen saturation; 6MWT performed twice to account for the known learning effect and the better walk distance recorded and used for exercise prescription; oxygen saturation and pulse rate monitored continuously throughout the 6MWT, with values recorded every minute; dyspnea during the 6MWT.

**Procedure:** See the Pulmonary Rehabilitation Toolkit (www.pulmonaryrehab.com.au) for details on how to provide pulmonary rehabilitation.

**Number of exercise sessions:** 16–24 sessions face-to-face

**Schedule details:** 2–3 sessions per week for 8–12 weeks, with at least an extra 1–2 sessions a week unsupervised at home

**Duration and intensity of each session:** Each session should be about 60 minutes. The session must include aerobic training at a starting intensity for ground walking of 80% of the 6MWT speed; starting duration 10–15 minutes building to 30 minutes by the 3rd–5th session; resistance exercises for upper and lower limb muscle groups of 8–10 repetitions x 2–3 sets of each exercise. For cycle and treadmill training intensity, refer to the Pulmonary Rehabilitation Toolkit.

Box 4: Exercise for patients with type 2 diabetes

**Rationale for exercise:** Traditionally, improving glycemic control has been the main focus of exercise interventions in patients with type 2 diabetes. However, many of the associated comorbidities are also relevant to prescribing exercise (e.g., obesity, osteoarthritis, peripheral neuropathy, falls risk, peripheral vascular disease and depression).

**Provider:** Physician referral to allied health provider or community fitness facility with competence in managing older adults with chronic disease. Prior to referral, physician screening for proliferative retinopathy, unstable angina, uncontrolled blood pressure, hyperglycemia or hypoglycemia, extent of peripheral vascular and neuropathic disease, and the presence of autonomic neuropathy (e.g., orthostatic hypotension, bradycardia or lack of sweating) may be indicated in patients with these comorbidities.

**Mode:** Aerobic exercise, resistance training and a combination of both are the most effective for glucose control. The combination offers the best treatment for both diabetes and common comorbidities and is recommended in current position statements. The exercise needs to be structured, which is defined as planned, individualized and supervised. Both group and individual training are effective. Patients with extensive comorbidities and frailty require more individualized training and supervision.

**Where:** Outpatient clinics of hospitals and health centres, allied health practices, community fitness facilities or at home with supervision

**Materials needed:** Aerobic exercise: good walking shoes, aerobic equipment if desired (treadmill, stepper, bike, etc.). Resistance training: free weights or machine-based training. Low-intensity training with bands or no equipment is not effective. A glucose-monitoring device, blood pressure cuff and easy access to high glucose drinks and snacks is recommended.

**Procedure:** Aerobic exercise should consist of large-muscle activities (e.g., walking, running, cycling and swimming) tailored to preferences and comorbidities, in particular to osteoarthritis. Resistance training (include multijoint exercises and large muscle groups) may include free weights or machine-based training (preferred for progression and safety in novices), with attention to rotator cuff disease and lower extremity arthritis that may require modification of exercises selected.

**Number of exercise sessions:** 2–3 sessions per week for resistance training; 3–5 sessions per week for aerobic exercise; continue indefinitely

**Schedule details:** Exercise may need to be timed to coincide with peaks of glycemia postprandially and should not be undertaken after insulin or oral hypoglycemic administration without eating a meal beforehand. Shorter sessions may be accumulated across the day to achieve the full duration. No more than two consecutive days without exercising. Aerobic and resistance training may be done on separate days, which may improve efficacy and feasibility.

**Duration and intensity of each session:**

- **Aerobic exercise:** Accumulate 150 minutes of moderate intensity (40%–59% VO2 reserve [the difference between the rate of oxygen consumption at rest and at maximal exercise] or heart rate reserve, or 55%–69% of maximum heart rate or rated perceived exertion of 12–13 on a 6–20 point Borg Rating of Perceived Exertion Scale) in 3–5 sessions per week; OR 75 minutes of vigorous intensity (60%–84% VO2 reserve or heart rate reserve, or 78%–89% maximum heart rate or rated perceived exertion of 14–16 on the 6–20 point Borg Scale) in 3–5 sessions per week.

- **Resistance training:** Moderate to vigorous intensity (rated perceived exertion of 15–18 on a 6–20 point Borg Scale), 8–10 exercises; 2–4 sets of 8–10 repetitions per set) in 2–3 sessions per week

**Other:** Progression is necessary for improvement. As soon as the intensity of the workload drops below the required levels, the workload (e.g., pace, incline and amount of weight lifted) should be increased to reach the intensity targets. Intercurrent illness or laser surgery may require temporary cessation of exercise and resumption at a slightly lower intensity until former levels are regained. Communication between the physician, diabetes educator and fitness professional is necessary for optimal management of all aspects of diabetes.
proliferative retinopathy, and orthostatic hypotension. In the systematic review that included 47 RCTs, 30 did not report adverse events. Of those that did, no major adverse events were reported and, in a few studies, minor events included musculoskeletal injury or discomfort, hypoglycemic episodes (in two studies) and cardiovascular disease events that were unrelated to the intervention.

**Chronic fatigue syndrome**

The most effective type, duration and intensity of exercise for chronic fatigue syndrome are unclear. Appendix 5 describes an example of one exercise intervention (graded exercise therapy).

**Evidence of benefit**

The evidence comes from a recent Cochrane review (eight RCTs involving 1518 participants) of exercise therapy compared with usual care, wait list, or relaxation and flexibility training. There was moderate-quality evidence for the effect of exercise on fatigue, with a mean reduction of 2.8 points (95% CI 1.57 to 4.07) on a 0–33 point scale (a lower score indicates less fatigue). Studies that used other scoring for the fatigue scale had similar results (see Appendix 2). In four RCTs (involving 489 participants, with moderate-quality evidence) that measured self-perceived changes in overall health, more participants in the exercise groups reported improvement than in the control groups (RR 1.83, 95% CI 1.39 to 2.40). Two RCTs (low-quality evidence) measured sleep, with a mean sleep score of 1.5 points (95% CI 0.02 to 2.95) lower in the exercise groups, with a lower score suggesting improved sleep quality. There was also low-quality evidence (five RCTs) for the effect on physical functioning, with mean scores 13.10 points (95% CI 1.98 to 24.22) higher in the exercise therapy groups. The review authors were unable to draw conclusions about the effect of exercise therapy on QoL, pain, anxiety, depression, use of health service resources and drop-out rate.

**Contraindications**

There are no absolute contraindications to exercise for patients with chronic fatigue syndrome.

**Adverse events**

There is limited evidence about adverse events. In the Cochrane review, serious adverse reactions (worsening symptoms and deterioration in function) were only reported by one study (n = 319) but were uncommon (two participants) in both groups (RR 0.99, 95% CI 0.14 to 6.97).

**Coronary heart disease and heart failure**

Patients should always work within their exercise tolerance and progress gradually. Initially, direct supervision of resistance training is advocated. Beneficial gains are possible in those at highest risk (e.g., a history of acute myocardial infarction with comorbidities or advanced heart failure) and in those who adhere to the prescription. For optimal care, exercise is only one component of a comprehensive program. Appendix 6 describes the possible components of this type of program.

**Evidence of benefit**

A Cochrane review of 47 RCTs (10794 participants with coronary heart disease who were predominantly male and middle-aged) found that exercise-based cardiac rehabilitation compared with usual care reduced overall mortality (RR 0.87, 95% CI 0.75 to 0.99) and cardiovascular mortality (RR 0.74, 95% CI 0.63 to 0.87) at 12 months or more, and all hospital admissions (RR 0.69, 95% CI 0.51 to 0.93) in the shorter term (< 12 months follow-up), with no evidence of heterogeneity of effect across trials. There was no reduction in the risk of total myocardial infarction or revascularization. The impact on QoL was unclear, with 7 out of the 10 trials that measured it reporting a significantly higher QoL in the exercise group, but a meta-analysis was not performed because of heterogeneity.

A recent Cochrane review of 33 RCTs (4740 participants with heart failure, mostly with heart failure due to reduced ejection fraction and categorized as New York Heart Association classes II and III) found that exercise-based rehabilitation compared with no exercise controls had no effect on all-cause mortality up to 12 months follow-up (RR 0.93, 95% CI 0.69 to 1.27). Compared with the control group, exercise-based rehabilitation reduced the rate, over one year, of all hospital admissions (15 trials involving 1328 participants; RR 0.75, 95% CI 0.62 to 0.92) and hospital admission specific to heart failure (12 trials involving 1036 participants; RR 0.61, 95% CI 0.46 to 0.80). There was also a statistically significant and clinically important improvement in disease-specific QoL (up to 12 months) in the exercise groups (13 trials involving 1270 participants; MD –5.8, 95% CI –9.2 to –2.4, on a 0–105 scale, where a lower score is better). The overall risk of bias across the trials was moderate.

**Contraindications**

Absolute contraindications to exercise for patients with coronary heart disease and/or heart
failure include unstable ischemia, uncontrolled heart failure or arrhythmias, uncontrolled hypertension or diabetes, acute systemic illness or fever, severe and symptomatic valvular heart disease or any other cardiac condition that the family physician believes is life threatening. 19

Adverse events

Vigorous exercise can trigger a cardiovascular event, particularly in people who are habitually sedentary. Potential harms of exercise among patients with established coronary heart disease or heart failure are a nonfatal cardiac arrest (about 1 per 115 000 patient-hours of supervised exercise in patients with heart disease; about half the rate in patients with heart failure) or death (about 1 per 750 000 patient-hours of participation). 19

Conclusion

Exercise is an effective but neglected treatment for many chronic conditions. However, similar to surgery, exercise is not a single entity but must be tailored to the condition. If exercise interventions are not implemented in a manner that is consistent with how they were used in trials (e.g., at a lower intensity, shorter duration or with different components), the fidelity of the intervention is compromised, and clinicians and patients cannot expect to realize outcomes similar to those achieved in the trials.

Unless clinicians can access sufficient details about exercise interventions to prescribe them, they either guess at how to use them or do not use them at all. General practitioners have identified the need for exercise details and resources to assist them with exercise prescription. 444 Even when a family physician may not be involved in delivering the exercise intervention, they should know the main elements of an evidence-based exercise intervention so they can discuss with patients and refer appropriately. We have summarized the available evidence to assist clinicians in using and prescribing exercise interventions in practice.

Exercise prescription also requires clinicians to be able to manage patients’ misconceptions, fears and motivation, particularly for those who are unwell. Although these are also challenges for pharmacologic interventions, the challenges are of a higher degree for exercise. However, the potential rewards for clinicians and patients make overcoming the challenges worthwhile.
